

Electromagnetic Waves: Seeing Objects and Color

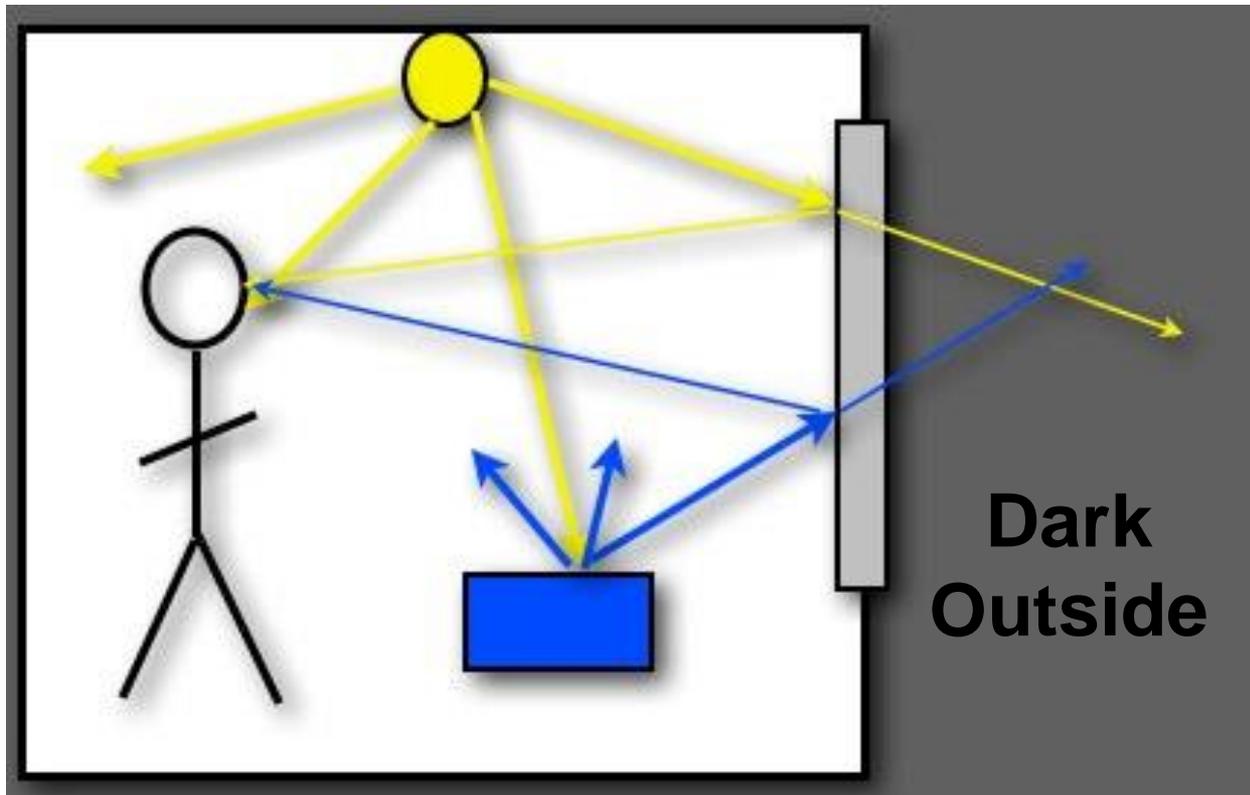

Electromagnetic Waves: Seeing Objects and Colors

Visible light is a small part of the electromagnetic spectrum that the human eye is capable of seeing

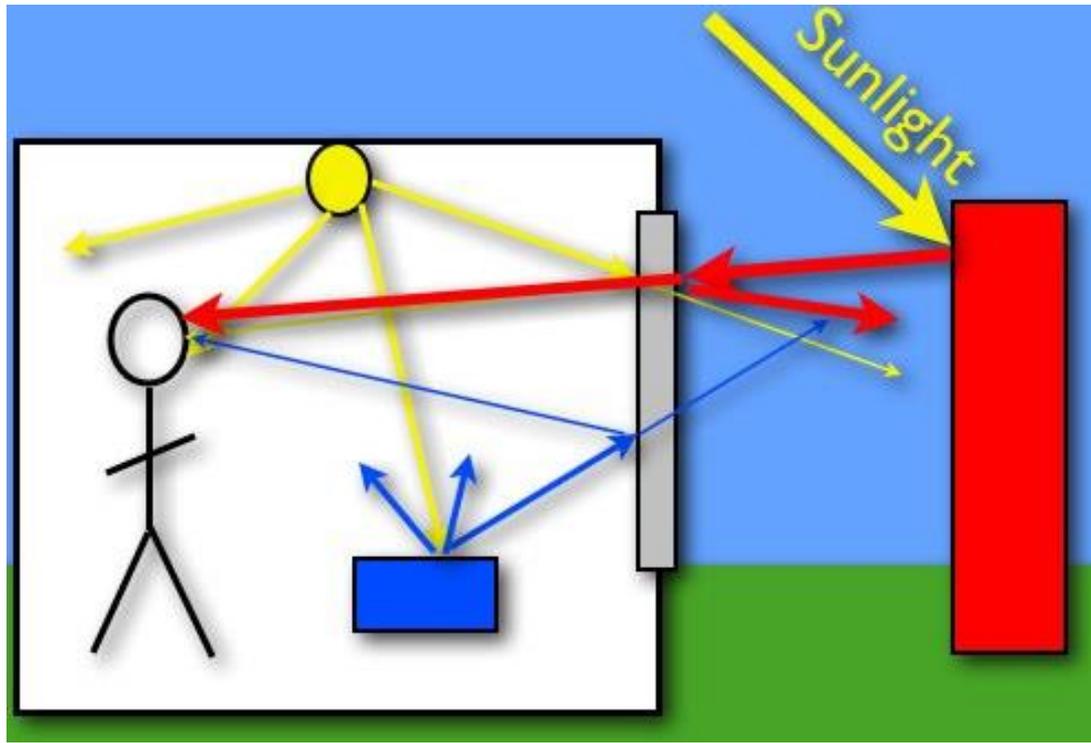

Electromagnetic Waves: Seeing Objects

- Objects can be seen if they are a source of light
- However, most objects around you do not give off light on their own. They can be seen only if light waves from another source reflect off them and into your eyes
- Light waves move in all directions from a light source

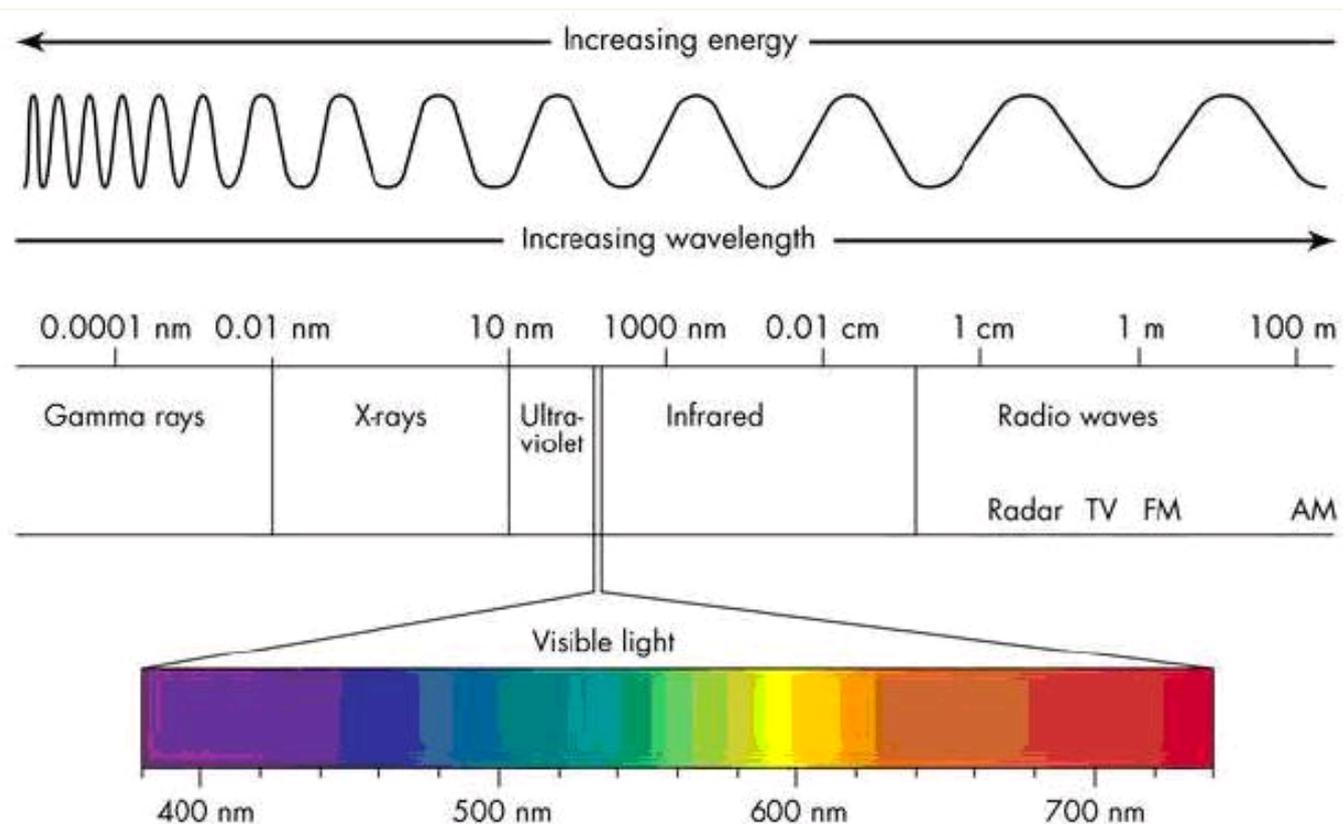

- The person can see the blue box because the light from the lamp (light source) reflects off of it (light as blue arrows).
- When light hits the window, some of it goes through the window and some reflects off the window.
- Some of the light reflected from the window goes to the person so that the person can see a reflection of the blue box and the light.
- Some of the light goes through the window. So, if you were outside in the dark, you could see the light and the blue box.

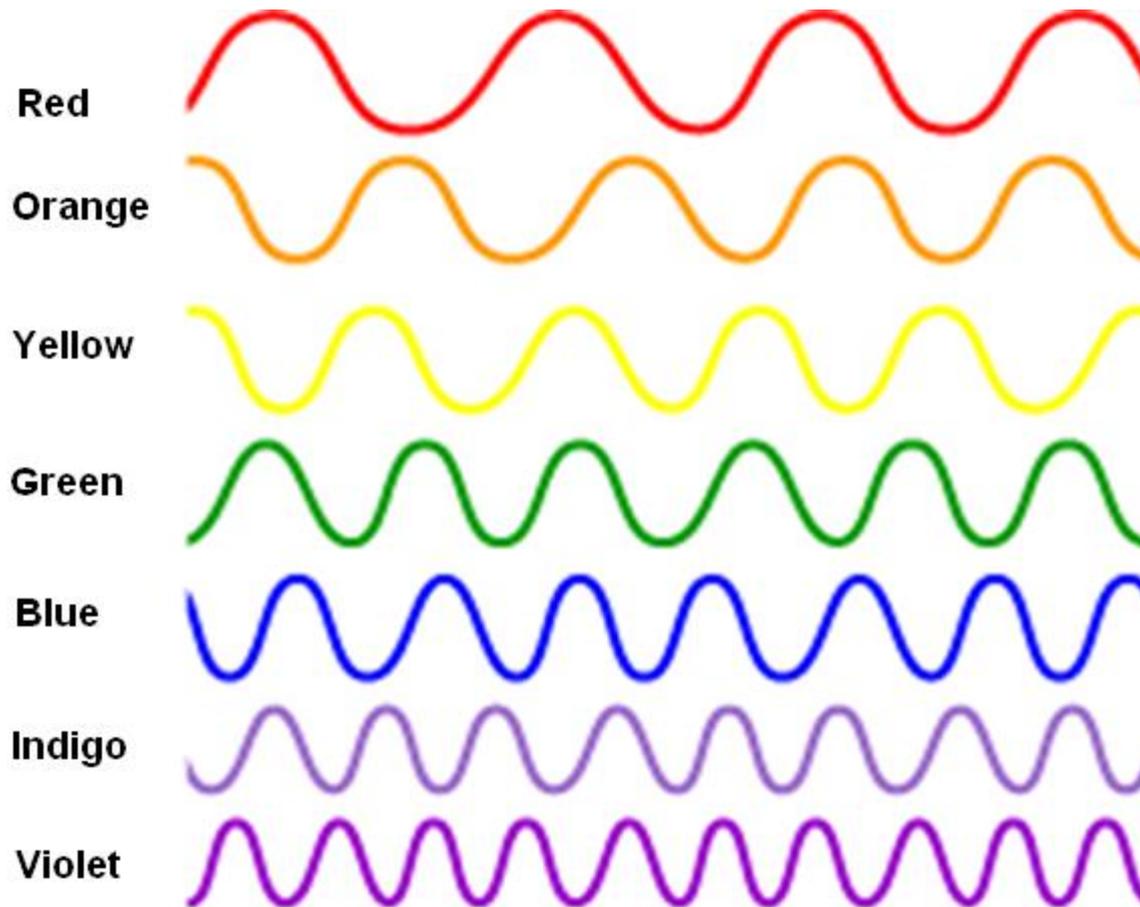

- Notice how the two light sources reflect off objects, which allows these objects to be seen.
- Additionally, light waves reflect in many directions, and only some of these enter your eyes.
- Remember, when waves strike an object, some are absorbed, some are reflected, and some pass through it. It depends on the material of the object.

Electromagnetic Waves: Seeing Color

Remember that visible light is a small part of the electromagnetic spectrum that the human eye is capable of seeing

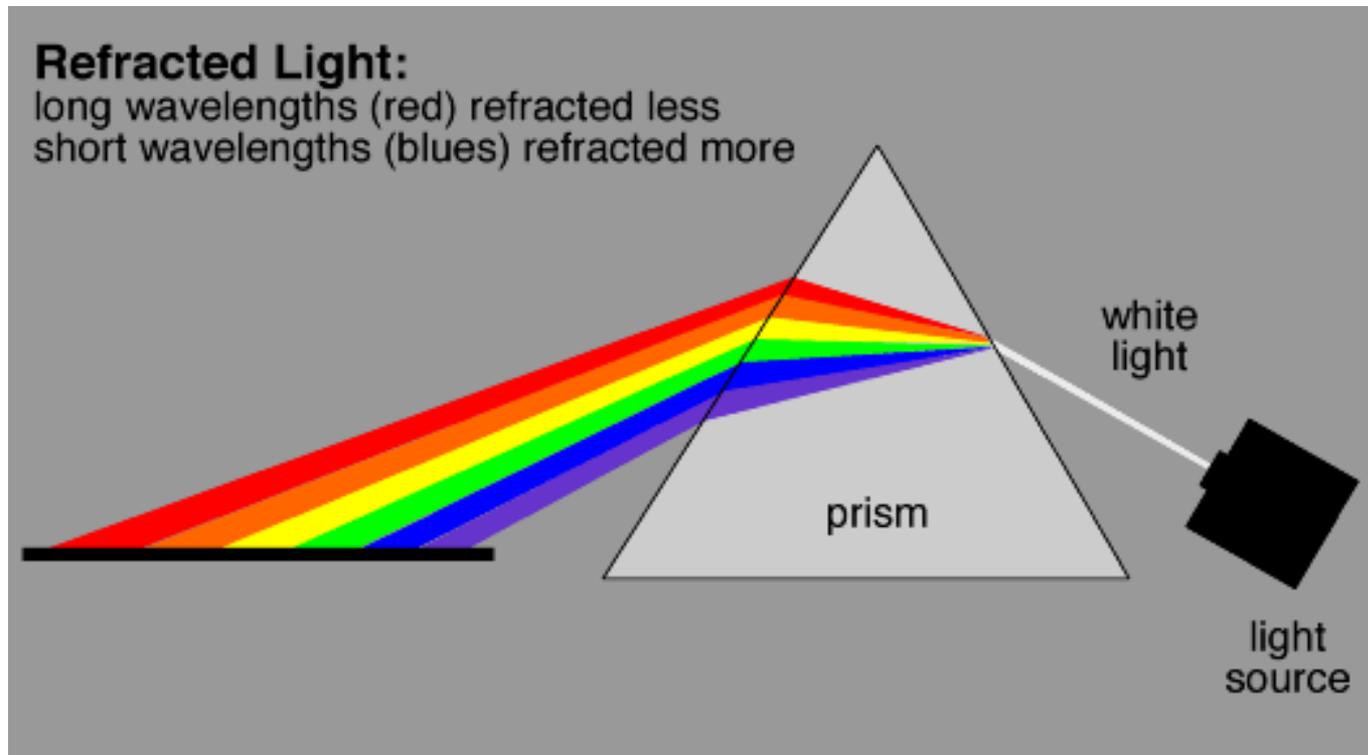

The colors of visible light are created by electromagnetic energy of various wavelengths (frequencies). See below

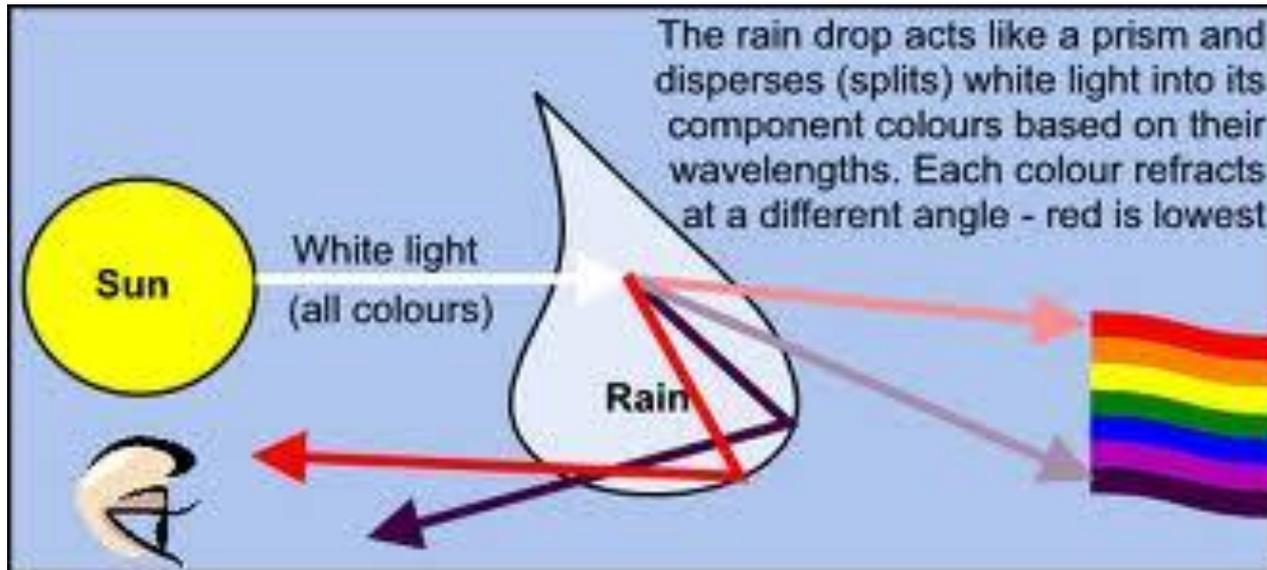

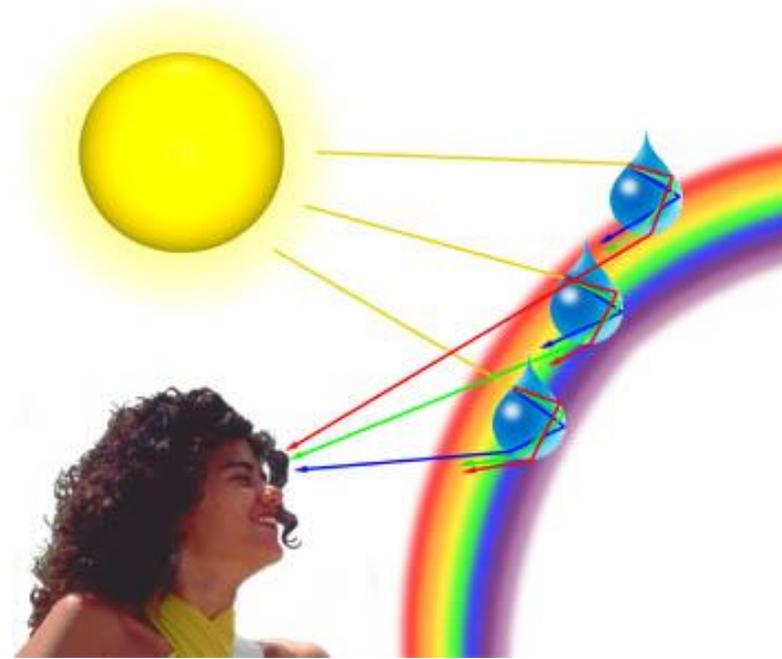

White light is made up of all the wavelengths of visible light.

When white light is refracted, it can be separated into its component colors.

As light passes through a prism, refraction causes light to bend and separate into many colors.

A rainbow is produced when a raindrop acts like a prism causing white light to refract (bend) and separate into many colors

Electromagnetic Waves: Seeing Color

- Humans see different wavelengths of light as different colors.

- Humans see long wavelengths as red

- Humans see short wavelengths as violet

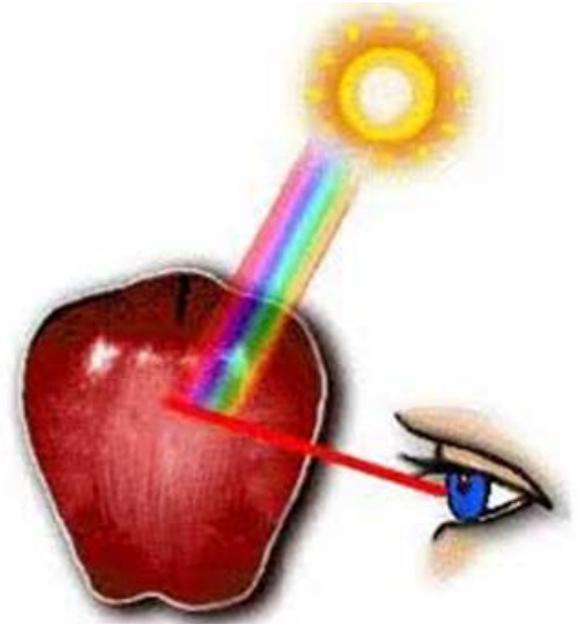

- Some colors, like pink and brown, are seen when certain combinations of wavelengths are present.

Electromagnetic Waves: Seeing Color

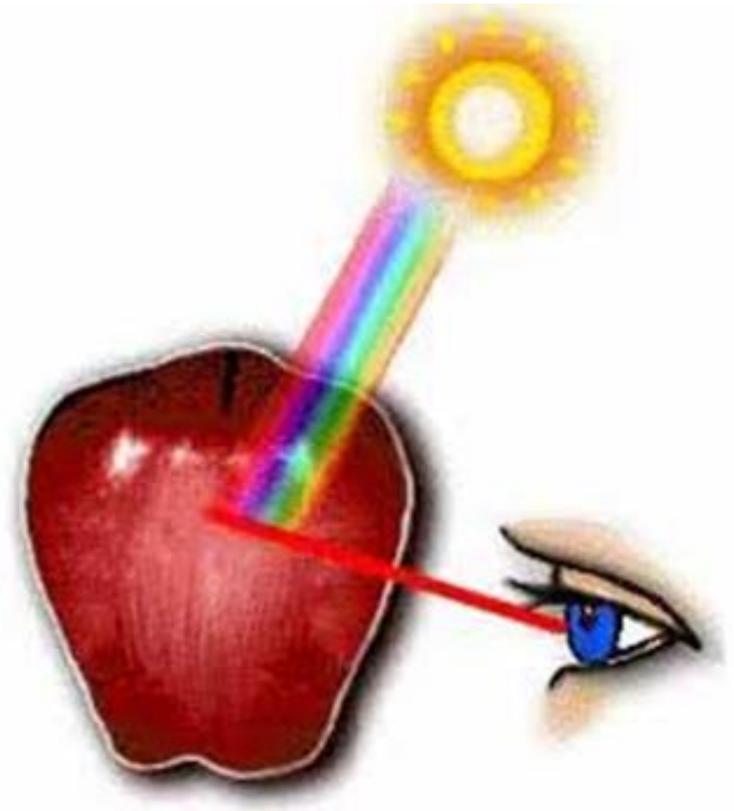

If we see an object because light is reflected off the object by a light source and white light is made up of all the wavelengths of visible light, why do objects have different colors?

The color of an object is determined by the wavelengths (color) of light it reflects. So, if an object reflects one wavelength (color), it absorbs all the other wavelengths (colors) of visible light.

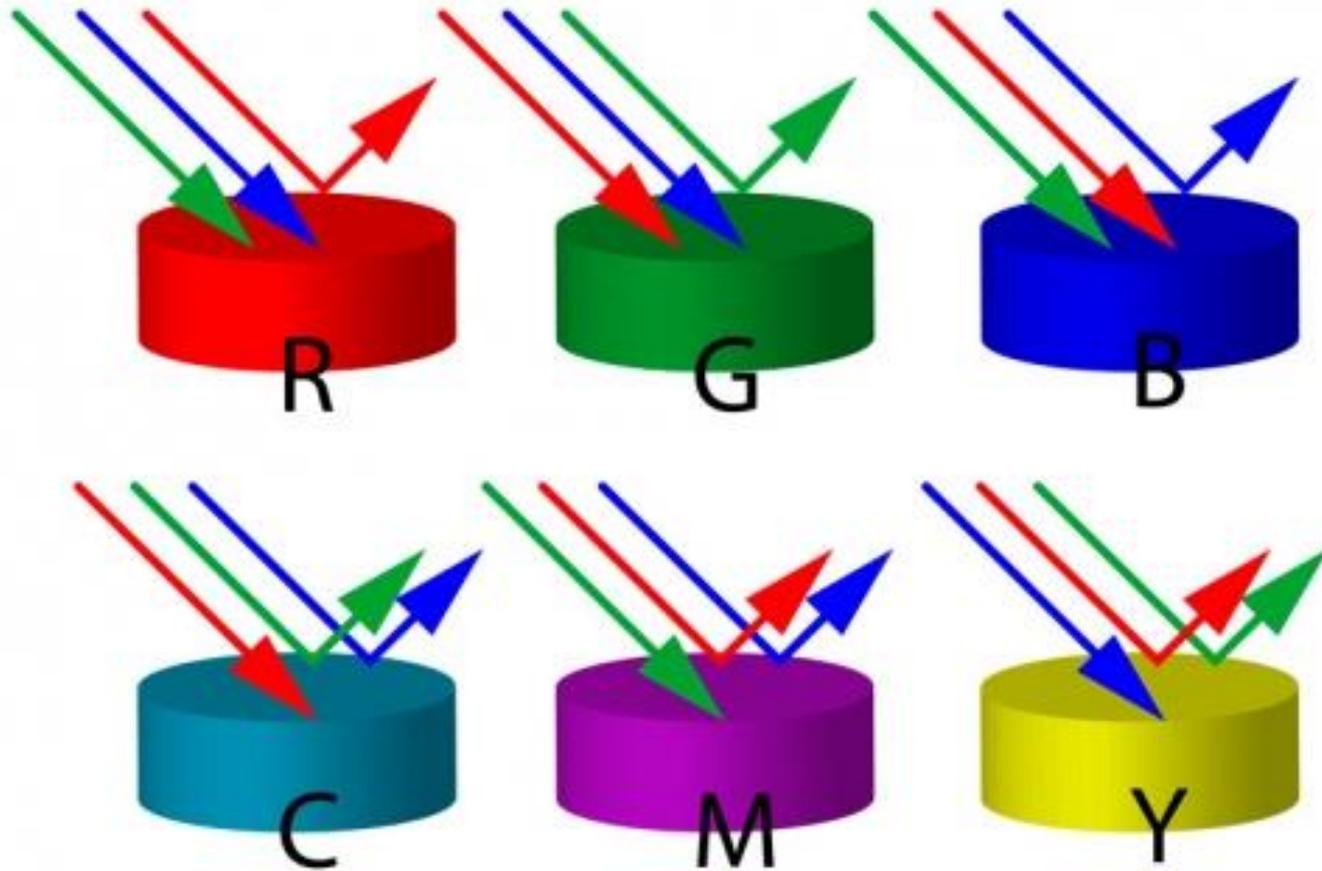

In this example, the sun is the light source. The sun's light appears white because it is made up of all the wavelengths of visible light.

However, humans see the apple as red because all of the other wavelengths (or colors) are absorbed by the apple. The wavelength that we see as red is reflected off the apple.

Absorption and Reflection

Seeing Color

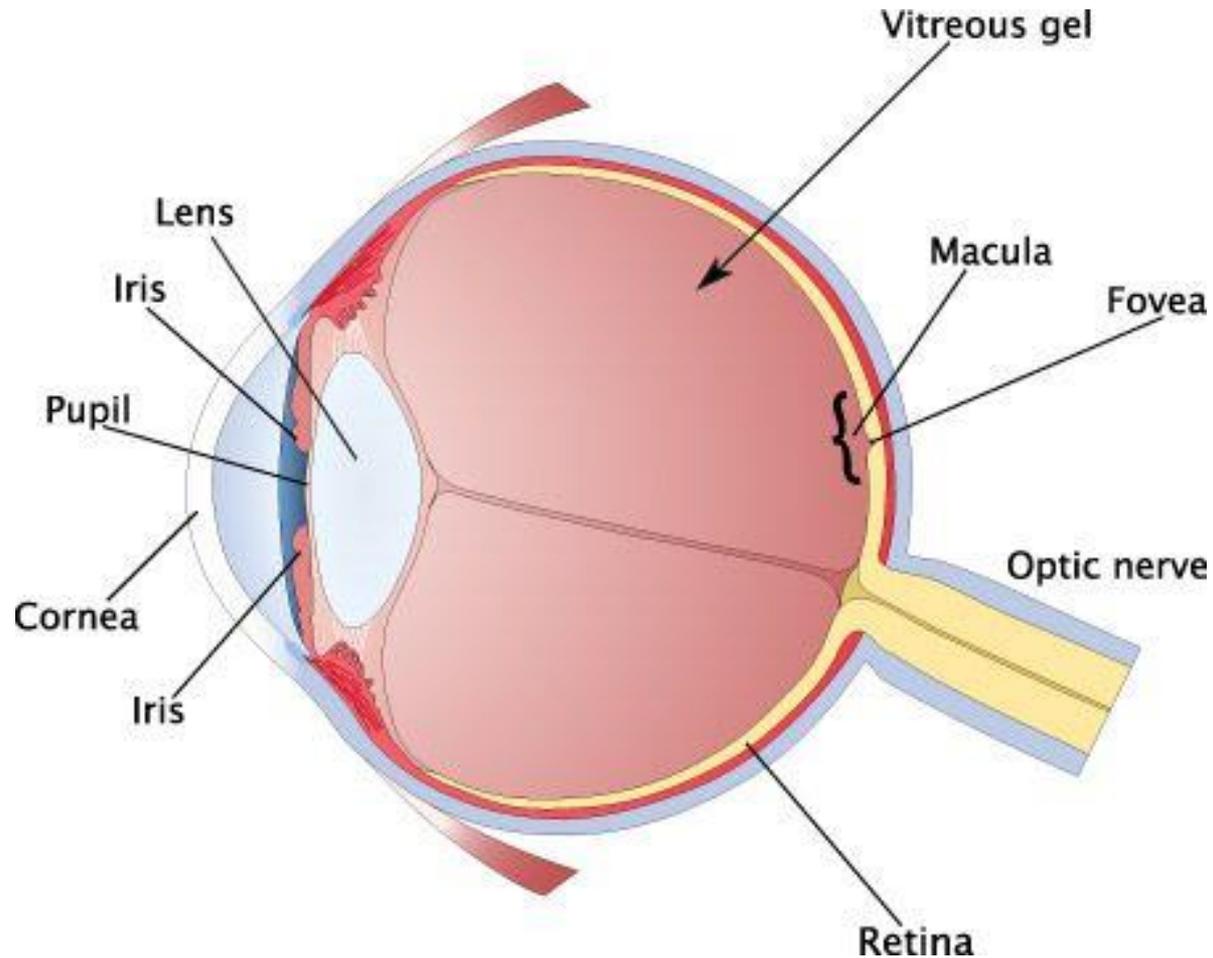

- An object that reflects all the light waves that strike it looks white

- An object that reflects none of the light waves that strike it (which means it absorbs all light waves) looks black

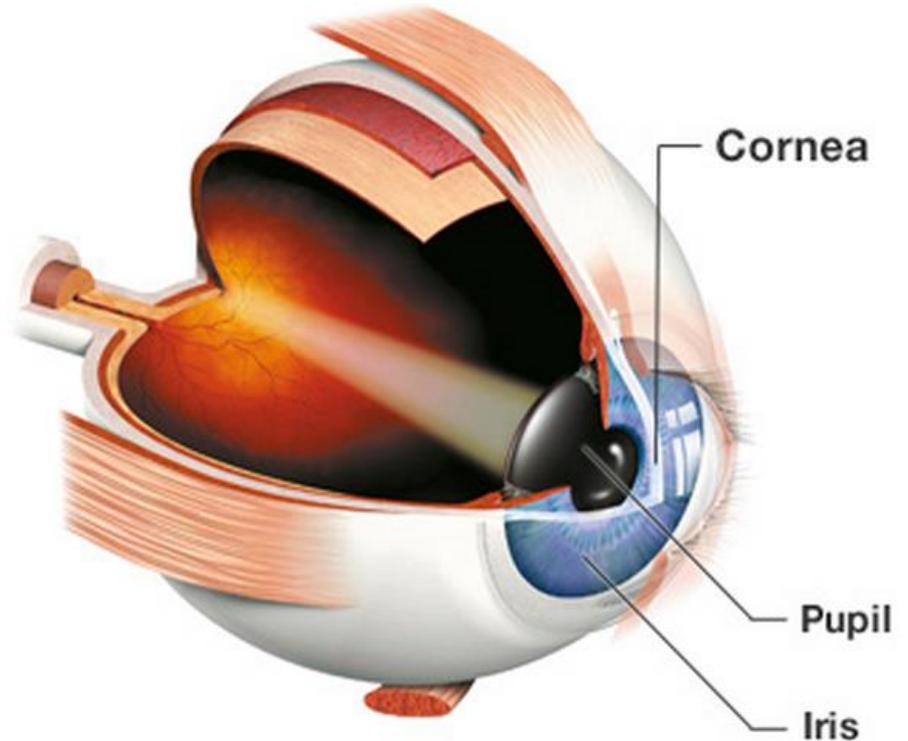

In a number of ways, the human eye works much like a digital camera

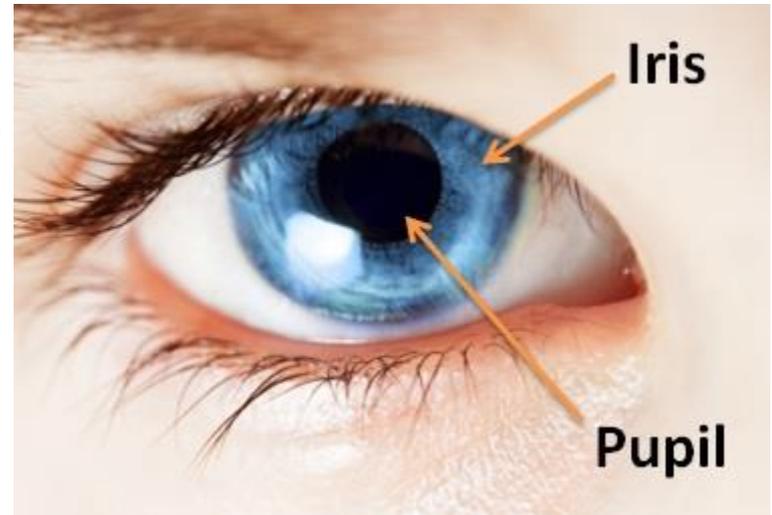

The Cornea

Light is focused primarily by the cornea — the clear front surface of the eye, which acts like a camera lens

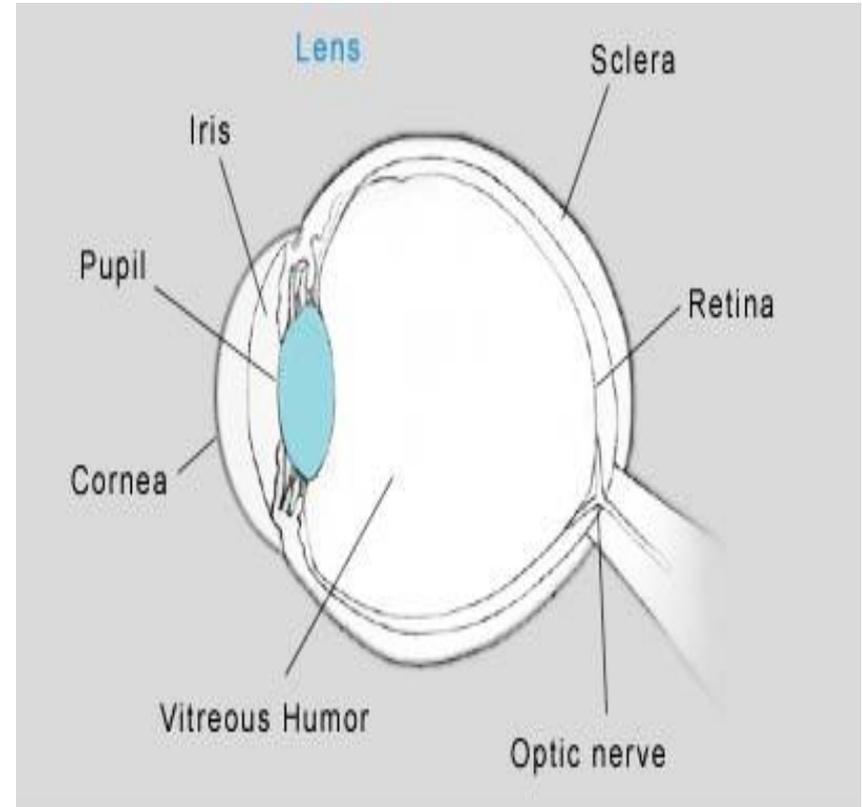

The Iris

The iris of the eye functions like the diaphragm of a camera, controlling the amount of light reaching the back of the eye by automatically adjusting the size of the pupil.

The Lens

The eye's crystalline lens is located directly behind the pupil and further focuses light. Through a process called accommodation, this lens helps the eye automatically focus on near and approaching objects, like an autofocus camera lens.

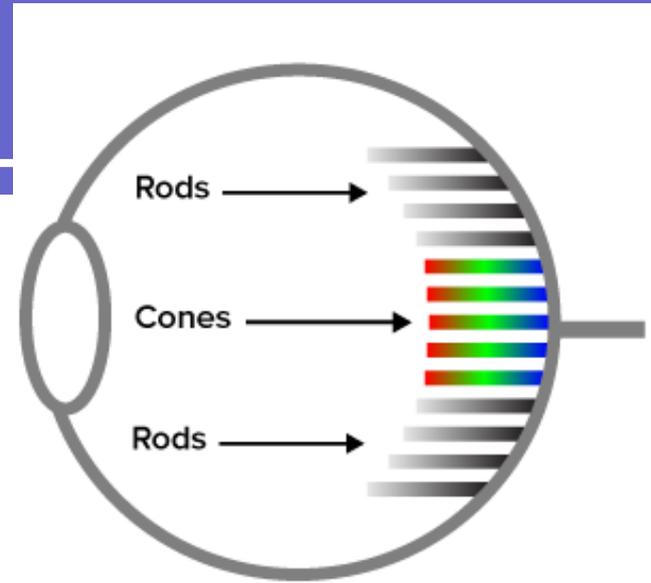

The Retina

Light focused by the cornea and crystalline lens (and limited by the iris and pupil) then reaches the retina — the light-sensitive inner lining of the back of the eye. **The retina acts like an electronic image sensor/screen of a digital camera,** converting optical images into electronic signals. The optic nerve then transmits these signals to the visual cortex — the part of the brain that controls our sense of sight

Rods

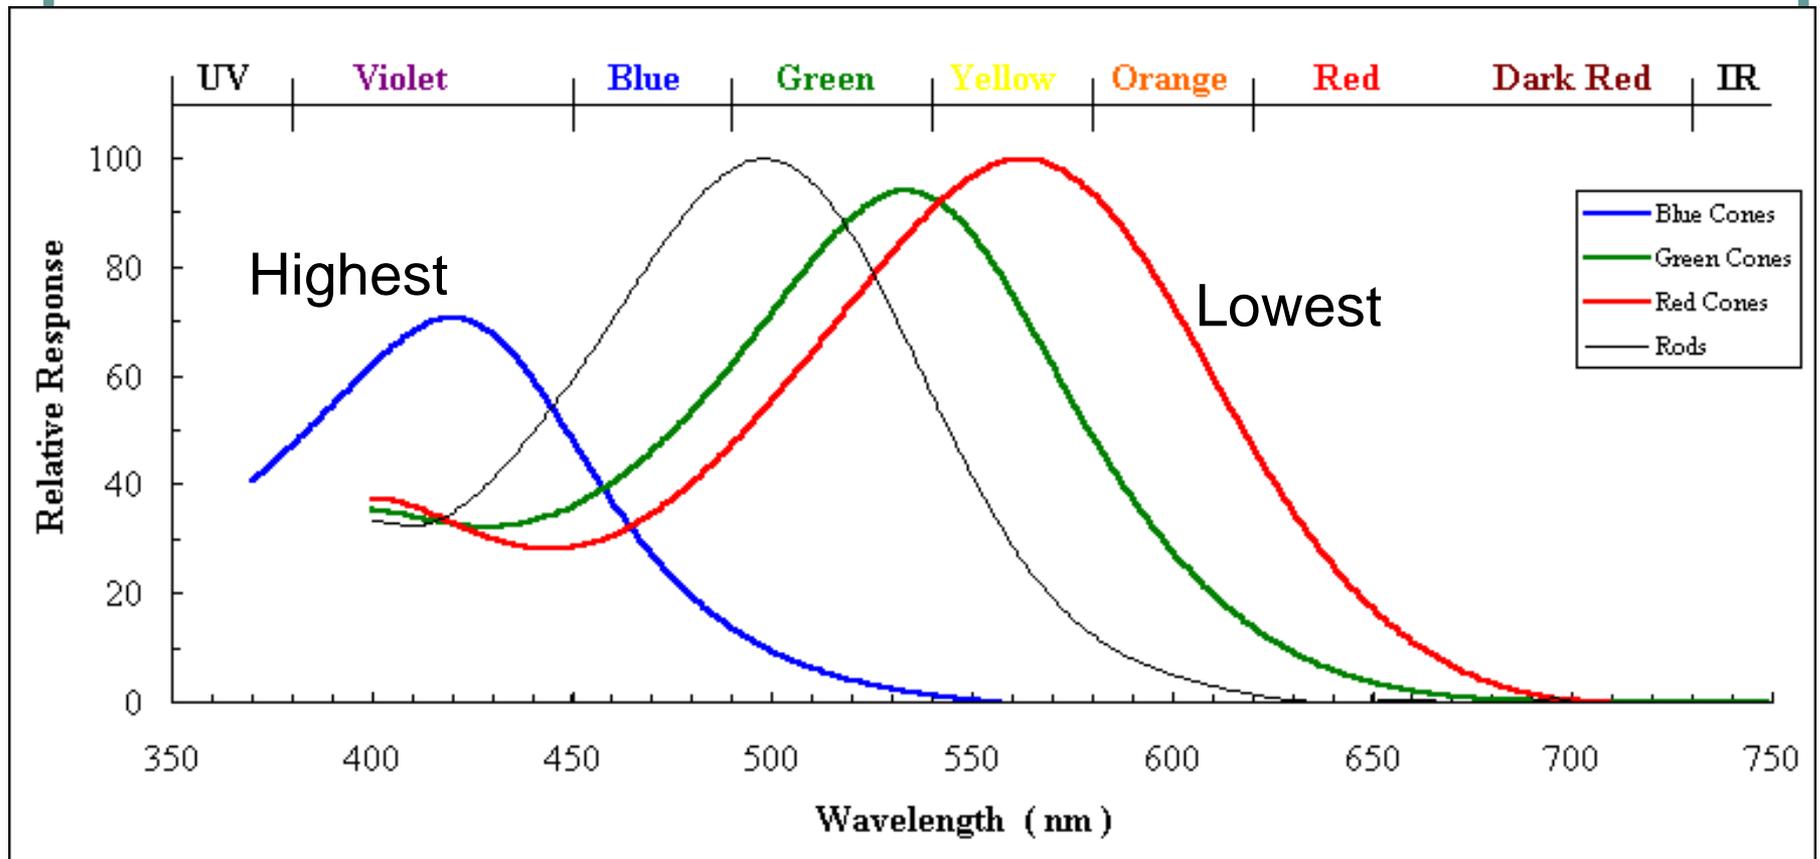

- **Rods:** See in black, white, and shades of gray and tell us the form or shape that something has. They are super-sensitive, allowing us to see when it's very dark.

Cones

Cones: Sense color and need more light than Rods to work well. Cones are most helpful in normal or bright light. There are 3 types of cones - red, green, and blue - to help you see different ranges of color. Together, these Cones sense combinations of light waves that enable our eyes to see millions of colors

Cones and Frequency

Your blue cones are capable of seeing the highest of frequency waves.
